INELASTIC INTERACTIONS OF HIGH-ENERGY PARTICLES IN RENORMALIZED STRONG-INTERACTION THEORIES

I. F. GINZBURG

Mathematics Institute with Computer Center, Siberian Division, Academy of Sciences U.S.S.R.

Submitted to JETP editor May 5, 1962

The expansion of the Green's functions and differential cross sections for inelastic processes in powers of the reciprocal of the energy $1/s$ is deduced in renormalized theories. In some cases the first terms of the series are the usual peripheral diagrams, whereas in other cases they are somewhat more complicated. The region of applicability of the results obtained is much larger than that for the usual pole theory of peripheral collisions.

Many recent papers are devoted to a description of strong interactions at high energies (see, for example, [1-3], where a detailed bibliography can be found). The corresponding processes are usually inelastic. They are frequently described by a peripheral model, according to which the most appreciable contribution to the matrix elements is introduced by diagrams with exchange of a minimum number of particles [2,4-6]. The experimental data apparently do not contradict such a model (see, for example, [1-3,7-9] etc.). However, in many cases doubts arise concerning the correctness of this model and the region of its applicability, because the theoretical premises on which the model is usually based are not very convincing, and the experiments so far have not been too accurate (the available exact theoretical results [10,11] are all unphysical and pertain to the case of large 4-squares of the momenta.

In the present paper we present for the analysis of strong interactions at high energies in renormalized theories a method which is sufficiently convincing theoretically. In many cases the results agree with the ordinary assumptions of the peripheral model of inelastic interactions, but there are also cases when the ordinary peripheral model is deformed in a certain manner.

The starting points in the developed construction are the general properties of renormalized theories, formulated for example in the book of Bogolyubov and Shirkov [12]. Unlike in other studies [4-6], the small parameter is $1/s$. Many of the assumptions which we must make here concerning the properties of the perturbation-theory series as a whole have not been demonstrated. These assumptions are quite usual, and are considered to be valid, for example, in electrodynamics. In meson theories their correctness raises grave doubts, but we cannot get along without them.

In the first section we consider the kinematics of the investigated inelastic processes as $s \to \infty$. They are divided into two types: processes in which the momentum transfer $l$ between the fast and slow particles and the momentum $p_0$ are such that $\lim_{s \to \infty} p_0 l / s^2 = u > 0$, and processes in which $\lim_{s \to \infty} p_0 l / s^2 = 0$. All further analysis will be made with processes of the first type as an example.

In the second section all the perturbation-theory diagrams for the given processes are subdivided into a finite number of groups of diagrams of given topology. It is shown further that with power-law accuracy the contributions of all the diagrams of a given topology to the Green's functions are the same. To compare the importance of diagrams of a given topology it is therefore sufficient to compare diagrams of the same topology, the high-energy parts of which correspond to the first nonvanishing approximate perturbation theory.

In Sec. 3 the known method of generalized diagrams [11,13] is developed for this purpose. This method is used in Sec. 4 to compare the importance of diagrams of different topologies. It turns out here that in the limit as $s \to \infty$ the main contribution to the Green's function of the process is made by diagrams of a certain specified topology, corresponding to exchange of one or a small finite number of particles between high-energy and low-energy blocks.

In Sec. 5 we consider the simplest properties of the corresponding expansion of Green's functions in powers of $1/s$ and the region of applicability of the results obtained.
1. FORMULATION OF THE PROBLEM AND KINETICS

A. We investigate inelastic scattering at energies, in which two groups of particles are formed: fast $\pi_1$ and slow $\pi_J$. We have $(\nu \geq 2)$

$$k_0 + p_0 = \sum_{i=1}^{\nu} k_i + \sum_{i=1}^{\nu} p_i, \quad 1 \leq i, j \leq \nu, \nu', \quad 0 \leq a, \beta \leq \nu, \nu';$$

(1.1)

$$k_0 = \mu_0^2, \quad p_0 = m_0^2; \quad \mu_0^2, m_0^2 \rightarrow m_i^2; \quad k_{0i} \geq 0.$$  

(1.2)

This process is described by a Green's function $G(k_0, p_0)$. The purpose of the present work is to study the asymptotic behavior of $G(k_0, p_0)$ at high energies in renormalized theory, under relations between $k_0$ and $P_0$ which will be considered below.

We introduce the momentum transfer between the fast and slow particles

$$l = k_0 - \sum_{j=1}^{\nu} k_j - \sum_{j=1}^{\nu} p_j, \quad p^t = t.$$  

(1.3)

The conservation law (1.1) has for fast particles the form

$$l + p_0 = \sum_{i=1}^{\nu} p_i.$$  

(1.3')

We put further

$$s = (k_0 + p_0)^2 = \mu_0^2 + m_0^2 + 2k_0p_0 = m_0^2 + \mu_0^2 + 2\mu_0E.$$  

(1.4)

B. Assume now that for all $\alpha, \beta, \gamma, \delta$

$$|k_0 p_0| \gg |k_0 k_0|, \quad s \gg |t|.$$  

(1.5)

In this case in the c.m.s., for example, the particles $p_0$ move forward and $k_0$ move backward. In the laboratory system of the particle $k_0$ ($k_0 = \mu_0, k = 0$), the $p_0$ are fast particles and $k_0$ are slow.

We now let $E$ and all the $p_0$ become infinite simultaneously for fixed $k_0$, so that

$$\lim_{s \rightarrow \infty} \frac{k_0 p_0}{s} = a_{3\alpha} = 0 \quad \left(\sum_{\beta=0}^{3} a_{3\beta} = 0\right).$$  

(1.6)

We are interested in the asymptotic behavior of $G$ with respect to $s$ at fixed $k_0$ [that is, fixed $l$ as well, cf. (1.3)]. Let us determine what limitations are imposed on $P_0$ in this asymptotic limit by virtue of (1.3), (1.5), and (1.6). We shall find it more convenient in what follows to operate in the laboratory system of the $k_0$ particle.

We denote by $b$, $f$ and $b'$, $f'$ respectively the numbers of fast and slow bosons and fermions

$$b + f = \nu + 1, \quad b' + f' = \nu' + 1.$$  

(1.7)

Conditions (1.6) denote that when $s \rightarrow \infty$

$$p_0^\nu = c_i E + o(E); \quad \sum_{i=1}^{\nu} c_i = 1, \quad c_i > 0, \quad c_0 = 1.$$  

(1.8)

Further, $p_0^{3\alpha} = p_0^{3\alpha} + m_0^{3\alpha}$, that is as $E \rightarrow \infty$ we have $|p_0^{3\alpha}| = p_0^{3\alpha} - m_0^{3\alpha}/2p_0^{3\alpha}$. Therefore, accurate to the constants in the quantities $p_1$ and $p_0$, we can assume that

$$|p_0| = p_0^{3\alpha}. $$  

(1.9)

The conservation laws (1.3) are now written in the form

$$p_0^\nu = E = \sum_{i=1}^{\nu} p_i - f_0;$$  

(1.10a)

$$|p_0| = E = \sum_{i=1}^{\nu} p_i x_i \rightarrow 1 \mid x_0; \quad |x_0|, \quad |a_{3\gamma}| < 1;$$  

(1.10b)

$$\sum_{i=1}^{\nu} p_i a_{3\gamma} = 1 \mid a_{3\gamma} = 0; \quad \gamma = 1, 2; \quad x_0 + a_{11} + a_{32} = 1.$$  

(1.10)

(here $x_0$ and $a_{\alpha\gamma}$ are the direction cosines of the vectors in a coordinate frame in which one of the axes is parallel to $p_0$). Here

$$p_0 a_{3\beta} = p_0 a_{3\beta} (1 - x_0 x_0 - a_{11} a_{11} - a_{12} a_{12}),$$

$$p_0 l = p_0 \left[l_0 - 1 \mid (x_0 a_{31} + a_{31} a_{31} + a_{32} a_{32})\right] = c_s S(l_0) + o(s).$$  

(1.11)

Relations (1.10a), (1.10b) and (1.8) for $l = \text{const}$ and $E \rightarrow \infty$ are compatible with one another only if asymptotically

$$1 - x_i = \frac{\mu_0 l_i}{\mu_0} + o\left(\frac{1}{E}\right) - \frac{\mu_0 l_i}{E} + o\left(\frac{1}{E}\right), \quad d_i > 0.$$  

(1.12)

It then follows directly from (1.10a), (1.10b), and (1.8) that

$$\sum_{i=1}^{\nu} d_i = 1 \mid p_0 (l_0 - 1 \mid x_0) = u \geq 0,$$  

(1.12a)

that is, (1.6) is satisfied asymptotically only if

$$p_0 l = s u + o\left(s \mid l_0 \right), \quad u \geq 0 \quad \left(l_0 \geq 0\right).$$  

(1.13a)

When $u = 0$ we should also have

$$l^t = t < 0.$$  

(1.13b)

From (1.10) and (1.12) we get as $E \rightarrow \infty$

$$a_{31}^2 + a_{32}^2 = \frac{2b_0}{E} + o\left(\frac{1}{s}\right) = \frac{2b_0}{E^2} + o\left(\frac{1}{s}\right).$$  

(1.14)

In this limit
\[ p_\alpha p_\beta = c_d s + o(s), \]
\[ \tan \theta_{ij} = a_{ij} a_{jk} / \sqrt{(1 - x_d^2)(1 - x_f^2)}; \]
\[ \sum_i p_i p_i = c_s (d_i + u_i) + o(s). \] (1.15a)

Thus, when \( \alpha \neq \beta \) and \( s \to \infty \), generally speaking, \( p_\alpha p_\beta \sim p_\alpha k_\gamma \sim s \), and in addition to (1.5)

\[ |p_\alpha l_\gamma|, |p_\alpha p_\delta| \sim s \gg |k_\delta k_\delta|, m_\theta. \] (1.16)

However, if

\[ p_{\alpha l} = o(s), \] (1.17)
all the \( d_i \) vanish and all

\[ p_\alpha p_\delta = o(s). \] (1.18)

Only in this latter case can the transverse momenta of all the particles \( p_\alpha \) (\( p_\alpha \sqrt{1 - x_d^2} \)) be of the order of a constant as \( s \to \infty \). With this, the subdivision of particles into groups \( p_\alpha \) and \( k_\beta \) is ambiguous, and the positions of the groups can be interchanged.

The experimental data on interactions at high energies \(^3\) show that such a subdivision is possible at least not too rarely. It is precisely the presence of such angular anisotropies that has given rise to the so-called peripheral models in multiple-production theories.

2. REPRESENTATION OF G BY MEANS OF DIAGRAMS AND THEIR CLASSIFICATION

A. Let us set in correspondence with \( G \) the series of the ordinary renormalized perturbation theory

\[ G = \Sigma G_\alpha. \] (2.1)

Here \( G_\alpha \) is one of the Feynman diagrams of the investigated process. The representation (2.1) involves certain difficulties. These were already discussed in \(^3\) and will not be analyzed here.

Let us present a certain classification of the diagrams \( G_\sigma \). The investigated process can not be represented by a sum of two independent processes. Therefore no singularities of the type of resonance denominators can occur in \( G_\sigma \), and the \( G_\sigma \) diagrams are all connected. We assume, in addition, that whatever divergences \( G_\sigma \) may contain have already been eliminated in the usual manner.

Let us now assume that the diagram \( G_\sigma \) can be broken up into strongly connected parts, which are linked in succession with the remaining parts only through one vertex each. Then \( G_\sigma = G_{\sigma 1} \times G_{\sigma 2} \times \ldots \times G_{\sigma k} \). We call the parts \( G_{\sigma 1} \) subdiagrams.

Let us now consider the \( "high-energy" \) part \( B_\sigma \) of the diagram \( G_\sigma \). The external lines for this diagram are \( p_\alpha \) and \( l_\beta \) (\( l_\beta \) are the lines of the set \( (b_\sigma, f_\sigma), 1 \leq \beta \leq n_\sigma \)). We have

\[ G_\sigma = B_\sigma \times A_\sigma. \] (2.3)

Here \( A_\sigma \) is the aggregate of all subdiagrams of \( G_\sigma \) which do not depend on \( s \) as \( s \to \infty \). The asymptotic properties of \( G_\sigma \) (and accordingly of the differential cross section \( T \)) with respect to \( s \) are determined by the properties of \( B_\sigma \), which we shall investigate later on.

B. We note first that

\[ B_\sigma = B_\sigma (s; x_\alpha, x_\beta, m_\beta^2; g_i), \] (2.4)

where \( s_\beta = p_\alpha p_\beta \), \( p_\alpha l_\beta \); \( x_\lambda = l_\alpha l_\beta, t_\alpha^2, t_\beta^2, m_\alpha^2, m_\beta^2 \) are the masses of the virtual particles on the internal lines of the diagram \( B_\beta \); \( g_i \) are the coupling constants of the theory. We also put \( y_\rho = s_\rho / s \), \( x_\lambda = x_\lambda / s, x_\rho = m_\rho^2 / s \). As \( s \to \infty \) we have \( x_\lambda x_\rho = 0 \).

From dimensionality considerations we see that

\[ B_\sigma = B_\sigma (s; x_\alpha, x_\beta, y_\sigma; g_i) = \prod g_i s^{N_\sigma} \Psi_\sigma (x_\lambda, x_\rho, y_\sigma). \] (2.5)

Here \( \Psi_\sigma \) is generally speaking the sum of products of \( \gamma \) and \( \tau \) matrices, taken with different weights. C. If we choose \( t_\alpha^2 = c_\alpha t_1^2, t_1^2 = 0 \) (\( c_\alpha \)-numbers), then all \( l_\alpha l_\beta = t_\alpha^2 = 0 \). If in addition we choose \( p_\alpha = m_\alpha^2 = 0 \), we obtain the diagram corresponding to the contribution of \( B_\sigma \) (\( s_\rho, 0, m_\beta^2, g_i \)). For the function \( \Psi_\sigma \) this means that \( x_\lambda = 0 \). In the vicinity of this point, as everywhere else, \( \Psi_\sigma \) is a continuous function for any fixed \( s \). Therefore for any \( \epsilon > 0 \)

\[ \lim_{x_\lambda \to 0} x_\lambda \Psi_\sigma (x_\lambda, x_\rho, y_\sigma) = 0. \] (2.6a)

Analogously, as \( m_\beta^2 \to 0 \) there can arise in \( B_\sigma \)
singularities of the infrared catastrophe type. Yennie, Frautschi, Suura, et al. \cite{11} have shown that these singularities factor out in polynomial fashion via the (logarithmic) singularities of lower orders of perturbation theory (although the analysis in \cite{11} is presented only with quantum electrodynamics as an example, it essentially does not depend on the form of the renormalized Lagrangian). Thus, as \( x_0 \to 0 \), there can arise in \( \Psi \) singularities only of the type \( \ln x_0 \), that is, for any \( \epsilon > 0 \) and fixed \( s \) we have
\[
\lim_{x_0 \to 0} x_0^\epsilon \Psi_\epsilon (x_0, x_\lambda; y_\delta) = 0. \tag{2.6b}
\]
The transitions to the limit in (2.6a) and (2.6b) are independent. We therefore can expect (2.6a) and (2.6b) to remain in force also when all the \( a_\lambda \) and \( m_\delta^2 \) tend to zero simultaneously. However, (2.6a) and (2.6b) have been written out for \( x_\lambda \) and \( x_0 \). They therefore signify also that for any \( \epsilon > 0 \)
\[
\lim_{s \to -\infty} s^\epsilon \Psi_\epsilon (a_\lambda/s, m_\delta^2/s; y_\delta) = 0. \tag{2.7}
\]
The obtained limiting relations show that, with power-law accuracy, the dependence of \( B_\sigma (s) \) is the same as in the topologically equivalent lowest-order perturbation-theory diagram.

### 3. GENERALIZED \( L_{\sigma \tau} \) AND \( T_{\sigma \tau} \) DIAGRAMS

A. We now form in accordance with the usual rules the matrix element of the investigated process
\[
F = \sum_{\sigma} F_{ss},
\]
\[
\rho = \bar{u} (k_0) \bar{u} (p_0) \gamma_{\mu} \sigma (p_\lambda) \ldots \bar{u} (p_v) \gamma_{\mu} (k_r) \ldots u (k_r).
\tag{3.1}
\]
We sum the quantity \( |F|^2 \) over all permissible states of the outgoing fast particles \( p_1 \) (including summation over the polarization states) and average the result over all polarization states of the particle \( p_0 \) and of the slow particles \( k_0 \).

The obtained quantity \( T \) is proportional to a certain differential cross section \( d\sigma / d\Omega \). Here, according to (3.1),
\[
T = \sum_{\sigma} T_{\sigma}, \tag{3.2}
\]
\[
T_{\sigma} \sim \sum_{I} F_{\sigma} F_{\sigma} dp_1 \ldots dp_v \delta (p_0 + l - \Sigma p_i) = \sum_{I} F_{\sigma} F_{\sigma} d\Omega.
\tag{3.3}
\]
We further sum \( T \) also over all the momenta of the particle \( p_0 \), that is, we form a quantity of the type \( \int dp_0 d\sigma / d\Omega \):
\[
L = \sum_{\sigma} L_{\sigma}, \quad L_{\sigma} = \int T_{\sigma} dp_0.
\tag{3.4}
\]
\[
L_{\sigma} \sim \sum_{I} F_{\sigma} F_{\sigma} dp_1 \ldots dp_v \delta (p_0 + l - \Sigma p_i) = \sum_{I} F_{\sigma} F_{\sigma} dQ.
\tag{3.5}
\]
The summation in (3.3) and (3.5) extends over all the values of the spin and other polarization variables \( k_0 \) and \( p_0 \), which are simultaneously admissible by the conservation laws for fixed \( k_0 \) (that is, as well as \( l \)).

In many investigations \cite{12} it was shown that the quantities \( L_{\sigma \tau} \) and \( T_{\sigma \tau} \) can be set in correspondence with certain generalized Feynman diagrams. Unlike the analogous ordinary \( M_{\sigma \tau} \) diagrams used in \cite{11} (see Fig. 1), the blocks \( G_{\sigma} \) and \( G_{\tau} \) in \( L_{\sigma \tau} \) and \( T_{\sigma \tau} \) are interconnected by the crossed lines \( p_\alpha (p_1) \). One of the crossed lines in \( L_{\sigma \tau} \) is directed opposite to all others. These crossed lines in \( L \) and \( T \) correspond to functions \( D^\alpha (p_\alpha) \), and not \( D (p_\alpha) \). This means that
\[
T_{\sigma} \sim \sum_{I} \left[ G_{\sigma} R (p_0) D^{\alpha} (p_0) dp_1 \ldots D^{\alpha} (p_v) dp_0 G_{\delta} \delta (p_0 + l - \Sigma p_i) \right],
\tag{3.6}
\]
\[
L_{\sigma} \sim \sum_{I} \left[ G_{\sigma} D^{\alpha} (p_0) dp_0 \ldots D^{\alpha} (p_v) dp_0 G_{\delta} \delta (p_0 + l - \Sigma p_i) \right].
\tag{3.7}
\]
Here \( R (p_0) = p_0 \pm m_0 \) if \( p_0 \) is a fermion, and \( R (p_0) = 1 \) if \( p_0 \) is a boson, while the summation extends over all polarization states of the particles \( k_0 \), so that \( L \) and \( T \) are numbers.

The generalized \( L_{\sigma \tau} \) and \( G_{\sigma \tau} \) diagrams are similar to the \( M_{\sigma \tau} \) diagrams introduced in \cite{11}.
\[
M_{\sigma} \sim \sum_{I} G_{\sigma} D^{\alpha} (p_0) dp_0 \ldots D^{\alpha} (p_v) dp_0 G_{\delta} \delta (p_0 + l - \Sigma p_i).
\tag{3.8}
\]
Unlike the customarily employed generalized \( T_{\sigma \tau} \) diagrams, the phase volume \( Q \) in the \( L_{\sigma \tau} \) diagrams is infinite.

We note also that by virtue of (2.3) the integrals in (3.3)—(3.8) contain only \( B_\sigma \) and \( B_{\tau} \). We can therefore rewrite (3.6) and (3.7) in the form
\[
T_{\sigma} \sim \sum_{I} A_{\sigma} B_{\sigma} R (p_0) D^{\alpha} (p_0) dp_1 \ldots D^{\alpha} (p_v) dp_0 B_{\delta} \delta (p_0 + l - \Sigma p_i) \tag{3.6a} \times \left\{ p_0 + l - \Sigma p_i \right\} A_{\tau} = \sum_{I} A_{\sigma} A_{\tau} A_{1} ,
\]
\[
L_{\sigma} = \sum_{I} A_{\sigma} A_{\tau} A_{1} . \tag{3.7a}
\]
Here \( A_{\sigma \tau} \) is a strongly connected generalized diagram.

\textsuperscript{1}Here, as in \cite{11}, the unperturbed Green's function of the corresponding field is \( D(p) \) for Bose particles and \( S(p) \) for Fermi particles.
B. We now determine, in analogy with the procedure used by Bogolyubov and Shirkov [12], the degree of growth or the index $\omega (\mathcal{L}_{\sigma \tau})$ of the diagram $\mathcal{L}_{\sigma \tau}$ in the following manner.

If we multiply all the $s_p$ by a factor $a$, fixing all the remaining parameters then we have as $s \to \infty$

$$\mathcal{L}_{\sigma \tau}(a s_p) \to a^{\omega(\mathcal{L}_{\sigma \tau})} \mathcal{L}_{\sigma \tau}(s_p).$$

(3.9)

Let further

$$\mathcal{J}_{\sigma \tau} = s^{\omega_s} \mathcal{H}_{\sigma \tau}(s);$$

$$\mathcal{J}_{\sigma \tau} = \left\{ \begin{array}{ll}
\mathcal{J}_{\sigma \tau} & \text{if } s > 0 \\
\infty & \text{if } s < 0
\end{array} \right.$$

(3.10)

Since $\mathcal{J}_{\sigma \tau}$ is finite, it follows from (3.3), (3.5), (3.9), and (3.10) that

$$\omega_s = \omega (\mathcal{L}_{\sigma \tau}) - 3.$$  

(3.11)

We shall be interested everywhere below in the quantity $c_{\sigma \tau}$. It separates with power-law accuracy the contributions from different diagrams in $\mathcal{L}_{\sigma \tau}$. Relation (3.11) makes it possible to replace an investigation of the quantity $c_{\sigma \tau}$ by a study of $\omega (\mathcal{L}_{\sigma \tau})$. The latter seems to us to be technically somewhat simpler.

4. DEGREES OF GROWTH OF THE $\mathcal{L}_{\sigma \tau}$ DIAGRAMS

A. We choose among all the $\mathcal{G}_{\sigma \tau}$ diagrams of given topology $(b_{\sigma \tau}, f_{\sigma \tau})$ those diagrams whose high-energy parts $B_{\sigma \tau}$ correspond to the first nonvanishing approximation $B^0_\sigma$ of perturbation theory. In such diagrams $B_{\sigma \tau}$ there are no closed cycles. Here

$$\mathcal{L}_{\sigma \tau}^0 \sim \int B_\sigma^0 D(s) \left. dp \cdots D(s) \right. \left. dp B_\tau^0 \delta \left( p_i + l - \sum_{i=1}^{n} p_i \right). \right.$$  

(4.1)

In Sec. 2 we have shown with power-law accuracy that in all the topologically equivalent diagrams the value of $B_{\sigma \tau}$ increases not faster than $B^0_{\sigma \tau}$ as $s \to \infty$. Therefore the estimate (4.1) of the degree of growth of the $\mathcal{L}_{\sigma \tau}^0$ diagram is the majorant of this estimate for all diagram pairs topologically equivalent to $B^0_{\sigma \tau}$ and $B^0_{\tau \sigma}$.

We denote the momenta on the internal lines of the $\mathcal{L}_{\sigma \tau}$ diagram by $q_1$ and $q_2$. Since the integration in (4.1) goes only over the crossed lines, to which the $D(s)$ corresponds, we can carry out the integration with respect to $p_i$. We are then left only with three-dimensional integrals of the type (2.5). Here

$$\mathcal{L}_{\sigma \tau}^0 \sim \int B_\sigma^0 \prod_{a} R(p_a) B_\tau \left( \frac{|p_a|^2 d |p_b|}{p_0^2} \right) \delta \left( p_a + p_b \right) \prod_{i=3}^{l} \left( \frac{|p_i|^2 d |p_l|}{p_i^2} \right)$$

$$\times \theta \left( 1 - |x_i| \right) dx_i.$$  

(4.2)

Integration in (4.2) is over the region

$$\sum_{i=3}^{l} p_i^2 \left( 1 - x_i \right) \ll \mu^2.$$  

B. Let $u > 0$ in (1.12a). Then, by virtue of (1.5) and (1.11) we have generally speaking $p_\alpha p_\beta \cdot p_\alpha l_\sigma = s_P \sim s$. This means that a contribution $\sim 1/s$ corresponds to each Bose line of the $\mathcal{L}_{\sigma \tau}^0$ diagram, while the corresponding contribution to each Fermi line is $\sim \hat{q}/s$.

If $\mathcal{L}_{\sigma \tau}$ contains closed Fermi cycles, then the products of pairs of factors $\hat{q}$ in the numerators of such cycles give quantities on the order of $s$. The function $f_{\tau} + f_{\tau}$ is even, and if any Fermi line enters in $\mathcal{L}_{\sigma \tau}$, it must go out of it. On such a Fermi line there are vertices in which a small momentum is transferred to the boson (if the boson is external with respect to $L_{\sigma \tau}$), and vertices in which a large momentum is transferred to the boson (if the boson is internal in $L_{\sigma \tau}$), as well as vertices from which a slow fermion emerges ("extreme").

In the vertices of the first of these types, in $L_{\sigma \tau}$, the contribution $\sim s$ gives a pair of factors $\hat{q}$, as well as on the lines belonging to the closed cycles. In the remaining vertices, each of the $\hat{q}$ makes a contribution $\sim s$ only if the composition of the corresponding group of slow $k_\alpha$ particles is not too "poor." Otherwise the contribution $\sim s$ is no longer made by each $\hat{q}$, but their number (of contributions $\sim s$) is larger than in the first case ($\hat{q} \hat{q} \sim s$).

Owing to kinematic limitations, the integration in (4.3) is essentially two-dimensional. Therefore the index of the vertex $\mu$, in which the Fermi line
belongs to the cycle closed in $X_{\sigma \tau}$, is $\omega(\mu) = 0$. This is also the index of a vertex where a small momentum is transferred to the boson. The indices of the remaining vertices $\mu$ are $\omega(\mu) = 1$. The summation of the factors $s$ is made more complicated in the general case by the presence of vertices with $\omega(\mu) = 1$ and also by virtue of the dependence of $\omega(\mu)$ on the composition of the external lines.

For each specific set $(b, f)$, $(b', f')$ we can readily obtain all the $\omega(X_{\sigma \tau})$ for different sets $(b_{\sigma}, f_{\sigma})$, $(b_{\tau}, f_{\tau})$. Thus, for sufficiently large $f'$, the maximum value of $\{ \omega(X_{\sigma \tau}) \}_{\text{max}} = \omega_{\text{m}}$ is realized for the following sets $(f_{\sigma} + f_{\tau}, b_{\sigma} + b_{\tau}) = (\varphi \beta)$:

etc. If $f' = 0$ then, by virtue of (2.2), $f_{\sigma} = f_{\tau} = 0$; if $f' = 2$, $b' = 0$, then, by virtue of (2.2), $f_{\sigma}$ is equal to 0 or 2. In both cases the maximum value of $\omega(X_{\sigma \tau}) = 2$ is attained when

$$b_{\sigma} = b_{\tau} = 1.$$

If $f' = 1$, then $f_{\sigma} = 1$ by virtue of (2.2) and the maximum value of $\omega(X_{\sigma \tau}) = 1$ is attained when

$$b_{\sigma} = b_{\tau} = 0.$$

It is also easy to see that at fixed $(b', f')$ and sufficiently large $(b, f)$, the maximum value of $\omega(X_{\sigma \tau})$ is attained at the minimum possible $n_{\sigma} = b_{\sigma} + f_{\sigma}$; $(b_{\sigma}, f_{\sigma} = b_{\tau}, f_{\tau})$.

In all these cases it is possible to arrange the terms in the sum (3.4) such that the change in $n_{\sigma} + n_{\tau}$ will correspond generally speaking to a reduction in $\omega(X_{\sigma \tau})$, that is, as well as in $c_{\sigma \tau}$ in (3.1) and (3.11).

5. EXPANSION IN POWERS OF $1/s$ AND PERIPHERALITY

A. We have shown above that the terms $T_{\sigma \tau}$ in the sum (3.2) for the differential cross section, which depend differenitely on $s$, correspond to diagrams $G_{\sigma}$ and $G_{\tau}$ of different topology. At the same time, the terms which depend in the same manner on $s$ (with power-law accuracy), correspond to diagram pairs $G_{\sigma}$ and $G_{\tau}$, of a few identical topologies. In particular, in each of the orders of perturbation theory, as $s \rightarrow \infty$ the quantity $T_{\sigma \tau}$ increases generally speaking, most rapidly for the pair of diagrams $G_{\sigma}$ and $G_{\tau}$ with the simplest topology, considered in the preceding section. Such a diagram $T_{\sigma \tau}$ makes the main contribution to $T$ in each order of perturbation theory. It is therefore natural to assume that their sum will also make the main contribution to $T$ as $s \rightarrow \infty$, regardless of the value of the coupling constant.

Additional account of some symmetries between different topologically equivalent diagrams can lead sometimes to changes in this hierarchy of the diagram classes. These changes can be taken into account by again considering the diagrams of the first vanishing orders of perturbation theory and then using a procedure similar to that carried out in Secs. 2 and 3.

Let us consider the sum of all the diagrams of topologically equivalent $G_{\sigma}$:

$$\sum_{b_{\sigma} = \text{const}} G_{\sigma}(b_{\sigma}, f_{\sigma}) = \Gamma_{\sigma},$$

Then

$$\sum \int \frac{R(p)}{2p_{0}} D^{(1)}(p_{1}) \cdots D^{(1)}(p_{n}) dp_{1} \cdots dp_{n} = \sum_{(b_{\sigma}, f_{\sigma}) = \text{const}} T_{\sigma \tau} = V_{\sigma \tau}.$$

In $\Gamma_{\sigma}$ and $V_{\sigma \tau}$ as well as everywhere below, $\sigma$ and $\tau$ number only the topology of the diagram. All the terms depend in identical fashion on $s$ in these sums.

We can now write sums that are already finite [by virtue of (2.2)]

$$G = \sum \Gamma_{\sigma},$$

$$T = \sum V_{\sigma \tau}.$$

By grouping in suitable fashion the terms in these
sums we obtain in (5.3) and (5.4) finite sums, in which the succeeding terms vanish compared with the preceding ones as \( s \to \infty \). If we assume that the \( V_{\sigma \tau} \) differ from one another by the same power of \( s \) as their terms \( T_{\sigma \tau} \) (this means that they are identically summed in some sense), then the sums (5.3) and (5.4) represent a certain expansion in powers of \( 1/s \). The dimensionless parameter of the expansion should in this case, of course, be one of the quantities

\[
e = |t| s^{-1}, \quad s^{-1} \sum m^2 \ll 1 \quad (5.5)
\]
or, what is more probable, the largest of them. (Here and throughout \( m_\alpha \) are the masses of the fast particles.)

Thus, as \( s \to \infty \) the principal terms in \( T \) can be represented in the form of one of the diagrams of the type of Fig. 2. We denote by \( \Phi_{\alpha i} \) the Green's functions of the blocks of slow particles of the diagram of Fig. 2. (For convenience we include in them also the propagation functions of slow virtual particles, which connect these blocks with the fast-particle block B.) Then

\[
G \to \prod \Phi_{\alpha i} \times \Phi_B. \quad (5.6)
\]

FIG. 2

B. It is easy to understand that when \( p_0 l = o(s) \) the situation is likewise analogous to that considered above. The corresponding analysis is more cumbersome than in Sec. 4, and will not be presented here. Generally speaking, however, one should pick out not one or two \( \Gamma_\sigma \) diagrams, but several. This is precisely why the usual somewhat naive picture of peripheral interactions at high multiplicity is customarily replaced by a crude hydrodynamic or statistical model. From our point of view, the interactions should be peripheral at high energies. This means that only a small part of the \( \Gamma_\sigma \) diagrams need by considered, generally speaking. For the analysis of these latter diagrams we can then use the results obtained at lower energies and lower multiplicity.

C. We thus arrive at the well known peripheral model, according to which the main contribution of the cross section at large energies is made by the \( \Gamma_\sigma \) diagrams with the "simplest" topology. In particular, for a whole series of processes the main contribution to the cross section is made by diagrams corresponding to the exchange of one meson between groups of fast and slow particles. Such processes are, for example, the processes \( (\gamma \pi) \pi + n \to 2\pi + n \), if the nucleons are slow, and the bosons fast. In other processes, such an \( n + \bar{n} \to k\pi + k_1K \), the principal term corresponds to exchange of one nucleon. In processes where the group of slow particles is sufficiently large and contains nucleons, while the group of fast particles contains none, the principal term is the one corresponding to the exchange of two nucleons, etc. The corresponding \( \Gamma_\sigma \) diagrams are shown in Fig. 2.

To find \( \Phi_{\alpha i} \) and \( \Phi_B \) we can use our knowledge of the simpler processes of lower multiplicity and lower energy. Thus, if the single-meson term is "principal," then to investigate the process \( (\gamma \pi) \pi + n \to n + k\pi + k_1K \), for some breakdown into fast and slow particles can be represented in the form of the diagram of Fig. 3a, it is sufficient to know the matrix elements of the processes of Figs. 3b-d.

We then have asymptotically

\[
G_B G_{\alpha i} \approx G_0 G_0. \quad (5.7)
\]

For a consistent execution of such a program it is necessary to know the phases of three out of four processes in Fig. 3. In practice, however, it becomes necessary to make some assumptions concerning the dependence of \( \Phi_B \) on \( t \). The simplest is the assumption that by virtue of (5.5) \( \Phi_B \) depends little on \( t \). Then the contribution from the diagram B can be replaced, accurate to \( \epsilon \), by the total cross section of the process

\[
p_0 + l = \sum_{l=1}^{l_2} p_l. \quad (5.8)
\]

Here \( p_0 l = s u \), and \( l^2 = \mu_1^2 \).

However, the considerations connected with the summation of infrared singularities (see Sec. 2 and [147]) and with the analytic properties of the \( S \) matrix (compare, for example, with [158]), force us to regard such an assumption as far from reality. On the other hand, the matrix elements \( \Phi_{\alpha i} \) can also depend on \( t \) in a different fashion merely because an estimate of the type (5.5) does not always hold for them. To study these elements we may need to know the matrix elements of processes of the type of Fig. 3b.
Usually \(^{3,4}\)the criterion of applicability of the one-meson approximation [the particular case (5.6)] is considered to be smallness of the quantity
\[
\kappa = (t - \mu^2) / M^2.
\] (5.9)
It is assumed here that \(\mathcal{G}_A\) and \(\mathcal{G}_B\) can be approximated by diagrams which correspond to real processes. The region of applicability of such an approximation is a priori not large (since the region where \(\kappa\) is small is not large). The available experimental data apparently confirm the correctness of such a one-meson approximation for several processes (see, however, \(^{13}\)). This is a particular case of our result (5.6), the actual smallness parameter being here not \(\kappa\) but \(\varepsilon\), and quite probably even \(\kappa\varepsilon\).

The experimental data on interactions up to 25–30 BeV (see, for example, the reviews \(^{3,8}\)) indicate that the contribution of the peripheral interactions to the cross section actually increases with the energy. In particular, it is shown in \(^{7,8}\) that the experimental data on nucleon–nucleon collisions at 1–10 BeV can be well explained by the peripheral model in a region which is incomparably broader than that in which \(\kappa\) is small. Inasmuch as large scattering angles are of low probability and the criterion (5.5) is satisfied almost everywhere, this result appears to be perfectly natural.

The proposed model with smallness parameter \(\varepsilon\) can also be used to describe other experimental data at \(\geq 10^5\) BeV \(^{16}\), which cannot be explained by means of the peripheral model with smallness parameter \(\kappa\) \(^{17}\). From our point of view, the increase in the role of two–center cases with increasing energy, as discussed in \(^{16}\), is quite natural.

D. At sufficiently high energies, the differential cross sections of all the inelastic processes should be described by such a peripheral model. The criterion for regarding the energy as high is apparently the satisfaction of the inequality
\[
\delta = (\Sigma m_a^2 + \Sigma m_b^2) / s \ll 1.
\] (5.10)
Inasmuch as the multiplicity increases with energy not faster than \(s^\alpha (\alpha < 1)\), all the interactions can be regarded as peripheral at sufficiently high energies. Therefore, at medium energies (5–25 BeV) the peripheral model describes poorly interactions with high multiplicity. For such interactions the value of \(\delta\) is not small.

In the described model it is difficult to draw any conclusions concerning the total cross section \((n' = b' + f' = 1, \nu' = 0)\). We can, however, attempt to obtain an estimate for the dependence of the cross section on the energy, postulating some connection between the power–law dependences of \(\Gamma_{\sigma}(s)\) and \(G_{\sigma}(s)\). If it is assumed that with power–law accuracy \(\Gamma_{\sigma}(s) \sim G_{\sigma}(s)\) as \(s \to \infty\), then the cross sections of all the inelastic processes decrease as \(1/s\).

Assumptions of this type establish some connection between the form of the Lagrangian and the degree of growth of the cross section as \(s \to \infty\) (cf. \(^{18}\)).

Let us assume that the \(V_{\sigma \tau}\) for the same process differently subdivided into groups of fast and slow particles differ from one another in the same power of \(s\) as their terms \(T_{\sigma \tau}\). Then, comparing the different terms \(T_{\sigma \tau}(s)\) with one another, we can obtain certain "selection rules" for the most "convenient" subdivisions into groups of fast and slow particles in the given process. These will make the main contribution to the total cross section at high energies.

E. We have shown above, under certain assumptions concerning the character of the summation of the perturbation–theory series, that at sufficiently high energies we can confine ourselves in the analysis of strong interactions to only a few diagrams of the simplest topology. The selection of these essential diagrams is determined by the character [which is unique! \((1.5), (1.15), (1.16)\)] of the subdivision of the particles into groups of fast and slow particles. To carry out this subdivision it is sufficient to examine diagrams of different topologies, in which the high-energy part is the diagram of the lowest nonvanishing order in perturbation theory with \(\nu + 1 + n_{\sigma}\) ends. In particular, for some sets of particles, the peripheral diagrams of the type 2a and b predominate, while for others, the predominating types are of type 2c and d—peripheral with "isobars," etc. The order of smallness of the terms discarded in the sums (5.1) and (5.2) is determined by the value of \(\varepsilon\). The region of applicability of the obtained results is therefore larger than the usual one defined by the parameter \(\kappa\) (see, for example, \(^{1,43}\)).

This result has been obtained in renormalized theory with zero vertex index. It is easy to understand how it varies if the index of the vertex is not zero. In either case, \(\omega(\mu) > 0\) or \(\omega(\mu) < 0\), the coupling constants are dimensional, but the result (2.7) and (2.5) remains valid with a natural change in the power of \(N_{\sigma}\) in accord with the dimensionality of the constant \(g_1\), which in the diagrams of the first orders of perturbation theory corresponds to a change in \(\omega(\mu)\).

In both cases the results of Secs. 2–5 remain in force for each order of perturbation theory. When \(\omega(\mu) > 0\), however, the diagrams of more "complicated" topology increase in each succeeding order of the perturbation theory no more slowly than the diagrams of the "simpler" topology in the preced-
I. F. GINZBURG

ing order of perturbation theory. Therefore in such—nonrenormalized—theories any conclusions concerning the most essential terms of $T_\sigma$ and $V_\tau$ are very risky. If $\omega(\mu) < 0$, to the contrary, the estimates made in Secs. 2-5 only become stronger with increasing order of perturbation theory. The general results of Sec. 4 are even more likely in this case than when $\omega(\mu) = 0$.

In conclusion I express my gratitude to A. Z. Patashinskii, V. V. Serebryakov, S. A. Khelfets, D. S. Chernavskii, and D. V. Shirkov for useful discussions.

Note added in proof (January 23, 1963). Recently the author became acquainted with\(^1\), where the experimental conditions were close to those considered in Sec. 1. In accord with the considerations advanced above, it turns out that at the investigated energies (12–17 BeV) the role of the peripheral interactions increases compared with the experiments carried out at lower energies.
